#### Abstract

Accurate time-series forecasting is essential for real-world applications such as predictive maintenance and feedback control. While deep neural networks have shown promise in recognizing complex patterns and predicting trends, their generalization capabilities are open to debate, and they typically do not perform well with limited data. In this paper, we examine the potential of time-series foundation models (TSFM) as a practical solution for addressing real-world (probabilistic) forecasting challenges. Our experiments using real building data demonstrate that, through fine-tuning TSFMs, we can achieve excellent predictions, even with limited data, and improve generalization in zero-shot prediction on unseen tasks.

#### Abstract

Accurate time-series forecasting is essential for real-world applications such as predictive maintenance and feedback control. While deep neural networks have shown promise in recognizing complex patterns and predicting trends, their generalization capabilities are open to debate, and they typically do not perform well with limited data. In this paper, we examine the potential of time-series foundation models (TSFM) as a practical solution for addressing real-world (probabilistic) forecasting challenges. Our experiments using real building data demonstrate that, through fine-tuning TSFMs, we can achieve excellent predictions, even with limited data, and improve generalization in zero-shot prediction on unseen tasks.

# 1 Motivation

Probabilistic time-series forecasting plays a crucial role in a range of real-world applications such as energy systems, especially as predictive models for anomaly detection based on confidence intervals or stochastic model-based predictive control. Deep forecasting models are especially useful when accurate and tractable first-principles models (e.g., a physics-based model) are difficult to obtain. Consequently, recent developments have focused on deep learning methods, which can identify patterns from historical data and provide predictions; c.f. DEEPAR [18], N-BEATS [15], and temporal fusion transformers (TFT) [13]. While deep learning approaches can yield accurate time-series forecasts [16], they also often produce unreliable forecasts, sometimes even under-performing compared to traditional statistical models like seasonal ARIMA or classical MLPs [10]. Moreover, for small datasets, these approaches are prone to issues like overfitting or mode collapse [7, 14].

Foundation models (FMs) [3] have recently emerged as a powerful tool, demonstrating excellent performance across numerous machine learning domains. The core idea of FMs involves leveraging a massive dataset to pre-train a large model, which can then be tuned to various downstream use cases. This approach contrasts with classical deep learning, which typically learns from scratch using task-specific data. Two primary advantages of FMs include: (i) their capacity to learn various function landscapes, allowing them to be expressive enough to contribute to different problem domains; and (ii) their strong generalization capability which can be attributed to exploiting patterns learned from a wide range of pre-training datasets. This generalizability is typically exploited for specific use cases or downstream tasks through a transfer learning process referred to as fine-tuning.

Despite their impressive track record in language and vision [4, 11, 17], their applicability and effectiveness in real-world time-series forecasting problems remain largely unexplored. This paper examines the effectiveness of *time-series foundation models* (TSFMs), *with emphasis on real multi-month data obtained from building energy systems*. In particular, we present four pressing research

NeurIPS 2024 Workshop on Time Series in the Age of Large Models.

questions and provide answers based on empirical studies using time-series signals collected from real-world building energy systems: (**RQ1**) *Zero-shot prediction quality*: How effective are baseline TSFMs? (**RQ2**) *Effectiveness of fine-tuning*: Can fine-tuning improve baseline TSFM forecasts? (**RQ3**) *Performance with limited data*: How do TSFMs perform on problems with limited data? (**RQ4**) *Generalization to unseen tasks*: Can TSFMs predict accurately on unseen systems?

# 2 Experimental Setup: Benchmark Models, Datasets, and Evaluation

**TSFMs:** Salesforce's MOIRAI [22], Google's TIMESFM [5], and Amazon's CHRONOS [2]. **Deep** Forecasting Models: LSTM[8]-based DEEPAR, N-BEATS, and TFT. See Appendix A for details.

For our experiments, we test the aforementioned forecasting methods on four different types of timeseries signals, collected at 15-minute intervals from SUSTIE, a Mitsubishi Electric's net-zero energy building, during office workdays. The signals include room occupancy (Occ), carbon emissions (CO2), power consumption for illumination and appliances (Light), and energy consumption for heating, ventilation, and air conditioning (HVAC) equipment (HVAC).

To reduce bias in the experimental results, we collected each time series from 8 zones spanning 3 floors (i.e., 3+3+2=8). Moreover, we conducted the experiments using 4 different cross-validation splits, each representing a different season through a blocked-split approach; each signal spans 3 months, resulting in 8 zones  $\times$  4 seasons = 32 different time series. For each time series, the last 2 weeks of signals are excluded and used as test periods. Based on the building's operational specifications, we used 24-hour signals as the context length (i.e., look-back period) to predict the following 4 hours. We conduct a rolling-window analysis [23] and report the mean  $\pm$  standard deviation error across these 32 time series.

# **3** Results

To evaluate the efficacy of different TSFMs compared to classical deep forecasting models such as TFT, we assess the performance based on: mean absolute scaled error (MASE), root-mean-squared scaled error (RMSSE), mean scaled interval score (MSIS), and weighted quantile loss (wQL); c.f. Appendix B for further details. Note that MASE and RMSSE evaluate the accuracy of the models' point predictions, while MSIS and wQL assess the quality of their probabilistic predictions. We compare against the popular N-BEATS which is deterministic: probabilistic metrics do not apply.

From Table 1, we observe the following. *Among the TSFMs*, TIMESFM and CHRONOS perform similarly, while MOIRAI generally exhibits the highest errors on our datasets. From the perspective

of distribution forecasting, CHRONOS consistently achieves the best performance amongst these three models. We attribute this to differences in the architectures and training methodologies, as this is in line with current conventional wisdom regarding generative models for continuous data (e.g., images), i.e., that models based on tokenized (i.e., discrete) representation often outperform models with continuous variables [19, 12]. In our case, we see CHRONOS, which operates on a tokenized representation of time series data and is trained via a classification cross-entropy loss, performing better than TIMESFM, i.e., a fully-connected network trained via a regression loss.

It is worth noting that our signals are not completely distinct but may share similarities with some of the pre-training datasets, such as PedestrianCounts, SpanishEnergyAndWeather, KDDCup2018, and AustralianElectricity. Nevertheless, the zero-shot performance of TSFMs falls short compared to models specifically trained on the downstream datasets, contradicting the original paper's claim of having comparable or occasionally superior zero-shot performance on new datasets. This discrepancy highlights the need for further examination, as discussed in Section 4.

Given that CHRONOS demonstrates the most promising preliminary performance, and its implementation is compatible with HuggingFace's Transformers library [21], we conduct the subsequent experiments using the CHRONOS models.

#### 3.2 Effectiveness of (Parameter-Efficient) Fine-Tuning (RQ2)

Next, we investigate whether we can potentially improve upon the (underwhelming) zero-shot performance of TSFMs with fine-tuning. Concretely, we test the effects of full fine-tuning (Full-FT) along with parameter-efficient fine-tuning (PEFT) via low-rank adaptation (LoRA) [9], which has shown promise in fine-tuning large language models (LLMs) but has been under-explored for TSFMs.

From Table 1, we deduce that *fine-tuning proves to be effective when applying TSFMs to our real-world data.* Fine-tuned CHRONOS clearly and consistently outperforms the benchmark deep forecasting models with both FullFT and PEFT with 1K fine-tuning gradient steps, sometimes reducing the error metric by more than 50%. We also check the impact of LoRA rank by varying r = 4, 16, and 64 for 1K training iterations; see Table 3 in Appendix C. Interestingly, Table 3 implies that LoRA is not only comparable, but actually outperforms (albeit marginally) Full-FT. This is consistent with the observations of LoRA in language tasks [9], and mainly because LoRA can prevent overfitting. Since the PEFT results are all similarly good, we recommend a lower rank (e.g., r = 4) to reduce the computational expense, for limited data and few FT iterations. In fact, using LoRA r = 4 reduces our total training floating-point operations (FLOPS) by 33% and accelerates training by 2.3×, compared to Full-FT, on a NVIDIA RTX2080Ti GPU with 6 CPU cores.

#### 3.3 Transferability with limited data (RQ3)

Figure 1: Forecasting accuracy by training dataset size on the Occ dataset.

So far, we have demonstrated that TSFMs can successfully forecast real-world building time-series data with fine-tuning. An immediate question is how much time-series data is needed to fine-tune such large models and whether a fine-tuned model can achieve high accuracy with less data. To explore this, we vary the training dataset size across periods of 1 week, and  $\{1, 3, 6, 9, 11\}$  months. For a fair comparison, we keep the evaluation period fixed while extending the training duration accordingly. The plot of forecasting accuracy across different models for the Occ signal is shown in Figure 1, with the tabulated results provided in Appendix C Tables 4–9.

When sufficient training data is available, TFT demonstrates performance comparable to that of TSFMs. However, the forecasting accuracy of both deep learning baselines and TSFMs declines as the training dataset size decreases. Notably, the performance gap between tiny datasets (e.g., 1 week) and sufficient datasets (e.g.,  $\geq 6$  months) is  $\approx 0.5 \times$  for CHRONOS compared to DEEPAR and TFT. This suggests that *TSFMs exhibit greater robustness to the small data problem*, presumably due to pre-training; pre-training enables models to capture general patterns from large datasets, which helps mitigate overfitting and enhances generalization [6].

#### 3.4 Generalizability to unseen tasks (RQ4)

In real applications, one is often faced with predicting time-series for a new client/user: i.e., with extremely little prior data available for training. In such circumstances, we evaluate the generalizability of TSFMs to unseen (but known to be similar) thermal zones. We fine-tuned CHRONOS using data for 3 months from a zone on the 2nd floor of our commercial building, and then tested it on the one from the 3rd (Table 2) and the other from the 4th floor (Table 10) without any additional tuning. As in the previous sections, we conducted tests on the four splits.

We observe that TSFM with fine-tuning outperforms TFT predictions comprehensively in terms of errors between point estimates. As in previous sections, LoRA r = 4 often does slightly better than Full-FT. The improvement of fine-tuned TSFMs over TFT is especially apparent from the Light and HVAC categories, where the TSFM competitors generalize significantly better due to an informative prior learned from a pre-training dataset containing energy data (albeit from a completely different source). For OCC and CO2 (which are correlated), since usage patterns across zones are not very dissimilar, TFT exhibits slight improvement in the probabilistic metrics, but is still outclassed by fine-tuned TSFMs. This demonstrates clearly how the pre-training prior of CHRONOS helps regularize the training and build predictions more robust to unseen patterns. With probabilistic forecasting deemed more complex, we surmise it is more susceptible to overfitting, occasionally competing against the benefits from the pre-trained prior and potentially explaining the few rare cases when TFT outperforms Full-FT on probabilistic metrics.

Table 2: Comparison of forecasting accuracy between TFT and TSFMs on *unseen* zone. The model is trained on a zone on the 2nd floor, then tested on another zone on the 3rd floor.

# 4 Conclusions and Open Opportunities

While the underwhelming performance of zero-shot TSFMs is understandable given that the models have not been exposed to real building usage data or a wide range of occupancy signals during pretraining, this highlights that TSFMs are still in the early stages of development and are not yet ready for plug-and-play with real-world applications. Instead of relying on in-context inference alone, our preliminary study indicates that to reach their full potential, current TSFMs require fine-tuning until they are scaled significantly to comprise billions of parameters, similar to LLMs, and capable of learning from a massive data corpus.

One open challenge is multivariate forecasting, which is especially critical to building energy systems whose time series are correlated, as they are produced by dynamics that are strongly connected between zones. Current TSFMs predominantly focus on univariate time series, while real-world data is often multivariate. Furthermore, the most effective method to integrate additional static and/or dynamic covariates into TSFMs remains unclear. Finally, an interesting open problem is to enable domain adaptation e.g. from commercial building data, how to transfer knowledge to improve residential building forecasting problems, or from the building level to the city level.

# Appendices

# A Benchmark Models

**Foundation Models** We use our base model on official implementations of three recently developed TSFMs: Salesforce's MOIRAI [22], Google's TIMESFM [5], and Amazon's CHRONOS [2]. Despite some minor differences, these models utilize transformers [20] as their underlying architecture, with 91M, 200M, and 200M parameters, respectively. They are all trained on publicly available datasets encompassing various domains such as energy, weather, stock, and synthetic time-series datasets.

**Deep Forecasting Models** We compare these TSFMs to three prominent deep learning baselines: LSTM[8]-based DEEPAR, N-BEATS, and TFT; all implementations use GluonTS [1].

# **B** Description of Performance Metrics

Let  $Y := \{y_1, \dots, y_t, \dots\}$  denote a time-series. The main objective of probabilistic forecasting is to predict the conditional probability distribution

$$\pi:=\pi(\overrightarrow{Y}_{t,P}\mid\overleftarrow{Y}_{t,C})$$

of the future target sequence

$$\overrightarrow{Y}_{t,P} := \{y_{t+1}, y_{t+2}, \dots, y_{t+P}\}$$

based on a past context sequence

$$\overline{Y}_{t,C} := \{y_{t-C+1}, y_{t-C+2}, \dots, y_t\}$$

for a given predictive window length  $P \in \mathbb{N}$  and context window length  $C \in \mathbb{N}$ . Errors are computed between model predictions  $\overrightarrow{Y}_{t,P}$  and ground truth  $\overrightarrow{Y}_{t,P}^{\text{true}} = \{y_{t+1}^{\text{true}}, y_{t+2}^{\text{true}}, \dots, y_{t+P}^{\text{true}}\}$ . Let the absolute mean error of a naive forecasting:

$$\zeta_{MAE} = \frac{1}{T-C} \sum_{\tau=C+1}^{T} |y_{\tau}^{\mathsf{true}} - y_{\tau-C}^{\mathsf{true}}|.$$

where T = |Y| is the length of a time-series. Similarly, let the root-mean-squared error of a navie forecasting:

$$\zeta_{RMSE} = \sqrt{\frac{1}{T-C}\sum_{\tau=C+1}^{T} |y_{\tau}^{\mathsf{true}} - y_{\tau-C}^{\mathsf{true}}|^2}.$$

The performance metrics chosen<sup>‡</sup> in the paper to evaluate model performance are as follows. Note that we do not want the metric to assign higher weights to easy-to-forecast sub time-series or (near) zero-series, since they, in fact, hold less practical importance in practice. Therefore, instead of using varying scales, we apply a constant scale across the series.

For MSIS, we use the 10% and 90% quantiles for lower and upper bounds, respectively. For wQL, we evaluate the 10%, 50%, and 90% quantiles..

#### B.1 Mean Absolute Scaled Error (MASE)

$$\mathsf{MASE}(\overrightarrow{Y}_{t,P},\overrightarrow{Y}_{t,P}^{\mathsf{true}}) = \frac{1}{\zeta_{MAE}} \cdot \frac{1}{P} \sum_{\tau=t+1}^{t+P} |y_{\tau} - y_{\tau}^{\mathsf{true}}|$$

<sup>&</sup>lt;sup>\*</sup>Note that the evaluation metrics are modified arithmetically to ensure a constant scaling factor.

## B.2 Root-Mean-Squared Scaled Error (RMSSE)

$$\mathsf{RMSSE}(\overrightarrow{Y}_{t,P}, \overrightarrow{Y}_{t,P}^{\mathsf{true}}) = \frac{1}{\zeta_{RMSE}} \cdot \sqrt{\frac{1}{P} \sum_{\tau=t+1}^{t+P} |y_{\tau} - y_{\tau}^{\mathsf{true}}|^2}$$

For the probabilistic metrics some additional notation is required. Suppose  $u_t = y_t^{(0.9)}$  and  $l_t = y_t^{(0.1)}$  respectively denote the upper (90th) and lower (10th) quantiles considered during evaluation,  $y_t^{(0.5)}$  denote the median, and  $y_t^{(\beta)}$  denote the  $\beta$ -th quantile for  $\beta \in (0, 1)$ , all at time t. Let  $\mathcal{I}(\cdot)$  denote an indicator function that is 1 when the parenthetical argument (usually a conditional statement) is satisfied, and 0 otherwise. Since we choose the 10-90 confidence interval,  $\alpha = 0.1$  denotes the 10% coverage parameter.

#### **B.3** Mean Scaled Interval Score (MSIS)

$$\mathsf{MSIS}(\pi, \overrightarrow{Y}_{t,P}^{\mathsf{true}}) = \frac{1}{\zeta_{MAE}} \cdot \frac{1}{P} \sum_{\tau=t+1}^{t+P} \left[ (u_t - l_t) + \frac{2}{\alpha} (l_t - y_t^{\mathsf{true}}) \cdot \mathcal{I}(y_t^{\mathsf{true}} < l_t) + \frac{2}{\alpha} (y_t^{\mathsf{true}} - u_t) \cdot \mathcal{I}(y_t^{\mathsf{true}} > u_t) \right]$$

#### B.4 Weighted Quantile Loss (wQL)

$$\mathsf{wQL}(\pi,\overrightarrow{Y}_{t,P}^{\mathsf{true}}) := \frac{1}{3} \left[ \mathsf{QL}^{(0.1)}(\pi,\overrightarrow{Y}_{t,P}^{\mathsf{true}}) + \mathsf{QL}^{(0.5)}(\pi,\overrightarrow{Y}_{t,P}^{\mathsf{true}}) + \mathsf{QL}^{(0.9)}(\pi,\overrightarrow{Y}_{t,P}^{\mathsf{true}}) \right]$$

where,

$$\mathsf{QL}^{(\beta)}(\pi, \overrightarrow{Y}_{t,P}^{\mathsf{true}}) = \frac{\frac{2}{P} \sum_{\tau=t+1}^{t+P} \left[ \beta \cdot \max(0, \ y_t^{\mathsf{true}} - y_t^{(\beta)}) + (1-\beta) \cdot \max(0, \ y_t^{(\beta)} - y_t^{\mathsf{true}})^{(j)} \right]}{\frac{1}{T-C} \sum_{\tau=C+1}^T |y_{\tau}^{\mathsf{true}}|}$$
